ABSTRACT

While the referent of a non-reflexive pronoun clearly depends on context, the nature of these contextual restrictions is controversial. The present study seeks to characterize one representation that guides pronoun resolution. Our focus is an effect known as “implicit causality”. In causal dependant clauses, the preferred referent of a pronoun varies systematically with the verb in the main clause (contrast *Sally frightened Mary because she...* with *Sally feared Mary because she...*). A number of researchers have tried to explain and predict such biases with reference to semantic classes of verbs. However, such studies have focused on a small number of specially-selected verbs. In Experiment 1, we find that existing taxonomies perform near chance at predicting pronoun-resolution bias on a large set of representative verbs. However, a more fine-grained taxonomy recently proposed in the linguistics literature does significantly better. In Experiment 2, we tested all 264 verbs in two of the narrowly-defined verb classes from this new taxonomy, finding that pronoun-resolution biases were categorically different. These findings suggest that the semantic structure of verbs tightly constrains the interpretation of pronouns in causal sentences, raising challenges for theories which posit that implicit causality biases reflect world knowledge or arbitrary lexical features.

Key words: pronoun resolution, implicit causality, thematic roles, psychological predicates, psych verbs, predicate decomposition

A proper name like *Catherine the Great* almost always refers to the same person: Catherine the Great. In contrast, a third-person pronoun like *she* can refer to a different entity each time it is used; thus the referent must be fixed by information in the context in which the pronoun is used. Some contextual cues – like pointing to an individual while uttering the pronoun (Nappa & Arnold, 2009)– simply pick out the referent by directing the listener’s attention to particular entity. The representational basis of other contextual cues, however, is less obvious. For instance, most English-speakers resolve the pronoun to Sally in (1) but to Mary in (2).

(1) Sally frightens Mary because she is a strange girl.

(2) Sally fears Mary because she is a strange girl.

This contrast suggests that the verb in the main clause can influence the resolution of the pronoun in the second clause, with “subject-biased” verbs like *frighten* leading to subject interpretations, while “object-biased” verbs like *fear* lead to object interpretations. This systematic difference between verbs cannot be solely attributed to the plausibility of the material after the pronoun. These verb effects are apparent even in cases where the sentence is cut off after the pronoun or the second clause has no meaningful content:

(3) Sally frightens Mary because she is a dax.

(4) Sally fears Mary because she is a dax.

This is a bias, however, and not an absolute constraint on our interpretation of the pronoun. For example, (5) and (6) are both coherent and plausible, though inconsistent with the bias, indicating that the content of the second clause can override the bias introduced by the verb.

(5) Sally frightens Mary because she [Mary] is so timid.

(6) Sally fears Mary because she [Sally] is so timid.

This systematic shift in pronoun interpretation depending on the verb is accompanied by a shift in our interpretation of the causal structure of the sentences. The notion of causation appears to be crucial. If the two clauses are linked by some other discourse relation (e.g., the second is a consequent rather than a cause) then the pronoun resolution biases will differ (Crinean & Garnham, 2006; Ehrlich, 1980; Kehler, Kertz, Rodhe & Elman, 2008; Stewart et al., 1998).

In a related finding, Brown and Fish (1983a) reported that people believe that Sally is responsible for Mary's fright in sentences like (7), and that Mary is responsible for Sally's fear in sentences like (8).

(7) Sally frightens Mary.

(8) Sally fears Mary.

Many of the verbs that have been found to be subject- or object-biased in pronoun resolution tasks have also been found to be subject- or object-biased, respectively, in the Brown and Fish causal attribution task (Rudolph & Forsterling, 1997). For this reason, both these effects, and a host of closely related phenomena, have been treated as a single construct which is generally called "implicit causality" (Brown & Fish, 1983a; Garvey & Caramazza, 1974; Garvey, Caramazza, & Yates, 1974).

Implicit causality (IC) provides a potential link between a linguistic process (pronoun resolution) on the one hand, and our conceptual understanding of the causal structure of the world and social relationships on the other. For this reason, it is of interest to a wide range of researchers. The phenomenon has been used to probe the development of causal schemas in children (Au, 1986; Corrigan & Stevenson, 1994), the stability of these schemas across

cultures (Brown & Fish, 1983b), and the conceptualization of social relationships and dominance hierarchies (Corrigan, 2001; LaFrance, Brownell, & Hahn, 1997; Maass, Salvi, Arcuri, & Gun Semin, 1989; Mannetti & De Grada, 1991). Psycholinguists have used IC as a test case for studying the interplay of bottom-up and top-down processing in language comprehension (Featherstone & Sturt, 2010; Garnham, Traxler, Oakhill, & Gernsbacher, 1996; Greene & McKoon, 1995; Guerry, Gimenès, Caplan, & Rigalleau, 2006; Koornneef & Van Berkum, 2006; Long & De Ley, 2000; McDonald & MacWhinney, 1995; McKoon, Greene, & Ratcliff, 1993; Shen & Yang, 2006; Stewart, Pickering, & Sanford, 2000; Pykkonen & Jarviki, 2010) and the developmental origins of these processes (Pykkonen, Matthews, & Jarviki, 2010). While some of these researchers have approached IC as an isolated phenomenon, others have addressed it as part of a broader theory of discourse coherence, treating it as a specific example of how the interpretation of one sentence is constrained by its relation to other sentences in the discourse (Frank, Koppen, Noordman, & Vonk, 2007; Kehler, Kertz, Rohde, & Elman, 2008; Crinean & Garnham, 2006; Ehrlich, 1980; Pickering & Majid, 2007; Stewart, Pickering, & Sanford, 1998). Other researchers have asked whether IC is an effect of language on thought or of thought on language (Brown & Fish, 1983a; Hoffman & Tschir, 1990) *a la* the Sapir-Whorf hypothesis (Whorf, 1956). Yet others have interpreted IC as an example of a cognitive heuristic, or short cut, and have used it to explore the effect of mood on the use of heuristics (De Goede et al., 2009; *cf* Forgas, 1995).

In the remainder of the introduction we review previous theoretical accounts of the mechanisms underlying IC, discuss reasons for revisiting one of these accounts (the *semantic structure* account), and provide an overview of the present experiments.

What is implicit causality?

Despite its wide application in psychology, the nature of IC is very poorly understood. While most authors agree that a verb's bias is due to its meaning, they disagree as to what aspect of meaning is relevant (Au, 1986; Brown & Fish, 1983a; Corrigan, 2001; Crinean & Garnham, 2006; Garvey et al., 1974; Garvey & Caramazza, 1974; LaFrance, Brownell, & Hahn, 1997; Maass, Salvi, Arcuri, & Gun Semin, 1989; Mannetti & De Grada, 1991; Rudolph & Forstering, 1997; Semin & Fiedler, 1988, 1991). While there are many differences between proposals, accounts can be roughly grouped into three types: the *arbitrary semantic tag* account, the *world knowledge* account, and the *semantic structure* account.

On the *arbitrary semantic tag* account, verbs have an implicit cause feature which does not reduce to any other aspect of the verb (e.g., it is not predicted by independent semantic, syntactic, or other features of/facts about the verb). Rather, each verb is marked in its lexical entry as being either subject-biased or object-biased, just as nouns in many languages are marked for gender. This serves as the null hypothesis about the basis of IC biases (that there is no other factor which predicts them) and is most explicit in work by Garvey and Caramazza (Garvey & Caramazza, 1974; Garvey et al., Caramazza, Grobery, Garvey & Yates, 1977).

On the *world knowledge account*, the implicit cause of the verb is inferred from learned distributional facts about situations to which the verb is typically applied. Much of this work is influenced by Brown and Fish's (1983a) demonstration that IC pronoun biases correlate with offline judgments of causal responsibility (see 7 & 8, above). Subsequent studies also demonstrated that the IC bias is modulated by the relative social status of the characters in the sentences, with higher-status individuals being seen as more causal (Corrigan, 2001; Maass, Salvi, Arcuri, & Gun Semin, 1989; Mannetti & De Grada, 1991; LaFrance, Brownell, & Hahn, 1997). These observations led many researchers to propose that IC is an inference

based on non-linguistic knowledge about who tends to cause certain types of events, rather than being derived directly from the literal meaning of the verb (e.g., Au, 1986; Koornneef & Van Berkum, 2006; Maass et al., 1989). That is, verbs do not encode any information about causality; rather, causality is inferred.

In contrast, the *semantic structure* account posits that IC bias is derived from the literal meaning of the verb. So while on the *world knowledge* account, changing facts about the world changes the IC bias of a verb, on the *semantic structure* account, facts about the world are relevant primarily in that they cause speakers to coin verbs that encode specific causal information. Brown and Fish (1983a) proposed the first such theory, systematically relating each verb's bias (subject-biased, like *frighten*, or object-biased, like *fear*) to the thematic roles of the verb's arguments. In linguistic theory, thematic roles are invoked to explain how the different arguments of a verb are syntactically realized and the range of syntactic contexts in which a verb can appear (for review, see Levin & Rappaport Hovav, 2005). Brown and Fish distinguished four thematic roles and a total of three types of verbs: agent-patient ("action") verbs, stimulus-experiencer verbs, and experiencer-stimulus verbs.

On this account, the subject of an action verb (*kick, paint, break, throw*) is an AGENT which effects some change on the PATIENT.¹ Because AGENTS are by definition causal actors (they cause the PATIENT to change), pronouns in sentences like (1-8) should be biased towards the subjects of action verbs. In contrast, there are two distinct patterns for transitive verbs that describe psychological states (called "psych verbs"). For some psych verbs (e.g., *frighten, confuse, surprise*) the subject of the verb is a STIMULUS, which elicits a psychological state in the

¹ Throughout, SMALL CAPS are used to refer to thematic roles.

verb's object (the EXPERIENCER). For other psych verbs, these roles are reversed: the subject is the EXPERIENCER and the object is the STIMULUS (e.g., *like, love, hate*). Like AGENT, the notion of STIMULUS is explicitly causal; therefore Brown and Fish argued that IC bias should follow the STIMULUS. Thus the stimulus-experiencer verbs (*frighten, confuse, surprise*) are subject-biased, whereas experiencer-stimulus verbs (*like, love, hate*) are typically object-biased.

The primary difficulty with this account is that numerous exceptions to these predictions have been found. Brown and Fish's (1983a) verb taxonomy has been revised several times, with mixed results. For example, Au (1986) identified numerous action verbs such as *thank* and *punish* which are object biased, contra Brown and Fish's predictions. These verbs were further investigated by Rudolph and Forsterling (1997), who labeled them "agent-evocator" verbs but were unable to determine anything that distinguished them from other action verbs beyond the fact that they are object-biased. In contrast, Semin and Fiedler (1988, 1991) suggested that subject-biased action verbs are those which do not entail a specific physical action (*stop, help*), whereas verbs which do entail specific physical actions (*punch, kick*) are only weakly (subject-)biased (note that their taxonomy, while similar to those above, does not invoke thematic roles). One obvious challenge for this taxonomy is that it does not predict any object-biased action verbs, despite considerable evidence that such verbs exist (Au, 1986; Rudolph & Forsterling, 1997). In addition, the fact that some researchers have identified verbs of intermediate bias (e.g., Garvey et al., 1974; Semin & Fiedler, 1991) has raised questions about apparently more categorical taxonomic theories.

The Present Study

Though there has been relatively little work on IC verb taxonomies in recent years (but see Crinean & Garnham, 2006; Ferstl, Garnham, & Manoulidou, 2011), there are reasons to

revisit the claim that semantic structure plays a role in pronoun resolution. First, the twenty-eight years since Brown and Fish (1983a) have witnessed an explosion of research in lexical semantics, with many semanticists arguing for considerably more complex and nuanced accounts of the semantic structure of verbs (Goldberg, 1995; Jackendoff, 1992; Levin, 1993; Pinker, 1989; Pustejovsky, 1995; Talmy, 2000a, 2000b; Van Valin, 2004; see Levin & Rappaport Hovav, 2005, for a review). While previous *semantic structure* accounts were based on relatively simple linguistic theories involving 4-5 thematic roles, current theories invoke a much richer set of theoretical primitives, allowing for more fine-grained distinctions. This can be achieved by positing a larger set of thematic roles (Baker, 1988; Kipper, Korhonen, Ryant & Palmer, 2008; Pesetsky, 1995), by treating thematic roles as prototypes based on a larger set of semantic features (Dowty, 1991), or by building verb semantics out of combinations of primitive predicates (Harley, 1995; Moens & Steedman, 1988; Pinker, 1989; Van Valin, 1993). Thus, in the analyses below we explore whether more modern theories of semantics can provide additional insight into IC. Second, most studies of IC bias have focused on a small set of verbs that have been repeatedly sampled (Rudolph & Forsterling, 1997), an approach which may have masked patterns in IC biases. Finally, there is a large body of work suggesting that much of the syntax-semantics interface is organized around notions of causality, and that causal information is encoded in the semantics of verbs in both English and other languages (Ambridge, Pine, & Rowland, 2008; Croft, 1991, *in prep.*; Lidz, Gleitman, & Gleitman, 2003; Naigles, 1990; Pesetsky, 1995; Pinker, 1984, 1989; Talmy, 2000). If these analyses are correct, it would be remarkable if such information did not play a role in IC, and, in fact, there is no evidence *against* semantic structure playing a role in IC biases. That non-linguistic factors such as social dominance also affect pronoun resolution has been taken as evidence in favor of

the *world knowledge* account, but data of this kind are not inconsistent with the possibility that semantic structure plays an independent and central role in generating causal inferences.²

The present study attempts to address these deficiencies in several ways. First, in order to provide a better understanding of the distribution of IC biases, in Experiment 1 we elicit biases for 720 high-frequency verbs, which were chosen irrespective of causal structure or IC bias. We find that earlier IC verb taxonomies fail to capture the pattern of results. In particular, in each taxonomy there are proposed categories which include a even mix of subject-biased verbs and object-biased verbs. Nonetheless, when we reanalyze these data according to more recent theories of semantics, we find new subclasses of verbs that have consistent IC biases. We then test the reliability and generalizability of these findings.

On the *semantic structure* hypothesis, there should be a relationship between the encoded meaning of a given verb and its IC bias. The fact that there is active debate about the nature of verbal structures (Levin & Rappaport Hovav, 2005) presents a challenge, as an account based on any particular theory could prove wrong even though the general approach is correct. We attempt to circumvent this problem by classifying verbs not based on primitives specific to a particular theory, but based on the data that all such theories attempt to predict:

² Interestingly, social dominance is only known to affect causal attribution tasks, such as those used by Brown and Fish (1983a). There is little evidence that such manipulations affect pronoun resolution (Goikoetxea, Pascual & Acha, 2008; Hartshorne, *submitted*; but see Ferstl et al., 2011).

the sentence frames a given verb can appear in.³ In particular, we classify our verbs according to VerbNet, which is an extension of Levin's (1993) analysis of verb argument structure applied to more verbs and supplemented with refinements suggested by Korhonen and colleagues (Korhonen & Briscoe, 2004; Korhonen & Ryant, 2005).⁴ 5,879 verbs are divided in 274 classes, primarily distinguished based on the types of arguments the verbs can take. Thus *please* and *like* are in classes 31.1 and 31.2, respectively, because the latter can take a *that* complement (*I liked that he was so honest*) while the former cannot (**I pleased that he was so honest*). Critically, verb classes consist of verbs that appear not just in the same individual

³ Not all theories of semantics are focused on such issues, and in principle IC bias could be related to an aspect of verbal semantics not relevant to the verb's distribution across sentence frames. We nonetheless focus on these frame-relevant semantic theories for three reasons. First, this is the notion of semantic structure invoked in IC *semantic structure* accounts such as Brown and Fish (1983). Second, the distribution of verbs across sentence frames is an objective, easily-observable phenomenon. Third, although theories of verb meaning vary along many dimensions, the same classes of verbs appear repeatedly across different theories (Goldberg, 1995; Jackendoff, 1992; Levin, 1993; Pinker, 1989; Pustejovsky, 1995; Talmy, 2000a, 2000b; Van Valin, 2004).

⁴ The primary difference is the addition of nearly two hundred subclasses. These subclasses play only a minimal role in the present analyses. In addition, the lists of verbs in each class are more extensive in VerbNet.

frame, but in the same set of frames (or alternations). For instance, the verbs in class 31.2 can appear in the following frames:

- (9) a. NP V NP (The tourists liked the painting.)
 b. NP V NP [for] NP (I liked him for his honesty.)
 c. NP V NP [in] NP (I liked the honesty in him.)
 d. NP V [that] S (I liked that he was so honest.)
 e. NP V S-ing (I like writing.)
 f. NP V NP S-ing (I like him wearing suits.)

Finally a small number of verb classes were divided according to what Kipper et al. (2008) call “considerations of meaning.” For instance, while *convert to* and *turn to* are highly similar in argument structure, in (10) the straw actually becomes gold, while in (11) the natives do not become Deism.

(10) The fairy turned the straw to gold.

(11) The missionaries converted the natives to Deism.

Importantly, these verb classes are empirical – rather than theoretical – constructs, which must be explained on any theory. Most theories of lexical semantics try to account for the existence of these classes by making reference to a smaller number of features which, in combination, generate all the classes. On some accounts, for instance, the syntactic behavior of a verb class is a product of the thematic roles the verbs in the class take or the sub-lexical predicates with which the verbal root can compose (Levin & Rappaport Hovav, 2005). For IC *semantic structure* accounts, what is important are these underlying features, not the verb class *per se*. Thus, the VerbNet classes may well be *more* fine-grained than is necessary. Nonetheless, we focus on these fine-grained verb classes because on all *semantic structure*

accounts, verbs within a class should behave uniformly with respect to IC, whereas which verb classes should behave similarly to one another may vary across specific theoretical proposals. However, in the General Discussion, we also evaluate two specific approaches to verb semantics.

Apart from any theoretical considerations, VerbNet offers notable advantages over other approaches. It is by far the most comprehensive semantic classification scheme for verbs and is available in electronic format on the Internet (verbs.colorado.edu/~mpalmer/projects/verbnet.html).

Experiment 1

In Experiment 1, we elicit IC pronoun biases for 720 high-frequency verbs. As shown in Table 1, existing IC verb taxonomies predict that most (Semin & Fiedler, 1991) or all (Brown & Fish, 1983a; Rudolph & Forsterling, 1997) verbs should show biases. The validity of these predictions is unknown, as to date our knowledge of IC has been based largely on a limited number of verbs selected primarily because they are known to have strong IC pronoun biases. In a thorough meta-analysis, Rudolph and Forsterling (1997) found that although dozens of studies had been conducted and 4 different languages had been tested, data on individual verbs had been reported for only 256 verbs, partly because many of the studies employed the same small set of verbs (but see discussion of Ferstl et al., 2011, in Appendix C). This narrow focus increases the risk of over-fitting the data. Thus, in Experiment 1, verbs were chosen solely on the basis of frequency and their ability to have both animate subjects and objects. We use these data to evaluate the verb classes proposed by Brown and Fish (1983a), Rudolph and Forsterling (1997), and the Linguistic Category Model (Semin & Fiedler, 1998, 1991), and then examine whether any of the classes proposed by VerbNet are systematic in their bias.

Method

Participants: Participants were recruited and tested online through coglanglab.org. We analyzed the data from the 1,365 participants who were native English speakers, reported not having participated in the experiment previously, and were over 10 years old ($M=29.9$, $SD=13$).

Materials and Procedure: As in previous studies, in order to create sentences with ambiguous pronouns, we selected verbs that allow both animate subjects and objects. Because we wanted a sample that was both as representative and unbiased as possible, this last criterion was applied loosely, leading to the inclusion of a number of verbs that are marginal with both animate subjects and objects, or allow them only when the verb is used in a dispreferred sense (see Appendixes A-B). We chose the 720 most common English verbs (Frances and Kucera, 1982) that met these criteria (Appendix A).

Each subject was tested on 25 verbs randomly sampled from the total set. In order to minimize the effects of words other than the verb on the judgments, all sentences were of the form *Sally VERBs Mary because she is a dax*. An example trial is presented below:

(12) Sally frightens Mary because she is a dax.

Who do you think is the dax?

Sally

Mary

The participant indicated his/her choice by clicking one of the names with the mouse. The order of the names (e.g., Sally, Mary) was randomized on each trial, with the grammatical subject sometimes being listed on the left and sometimes on the right. Participants were told a dax is a type of person, but given no more information. The same novel word was used for all trials; randomization of items across participants should mitigate any systematic order

effects. The names (e.g., *Sally* and *Mary*) were chosen randomly without repetition for each participant from a list of common American female names taken from a recent census. All sentences were presented visually.

Participants were given two example sentences and encouraged to recognize the ambiguity of the pronoun (e.g., *Sally helps Mary because she is a dax. You might think that daxes are very helpful and that Sally is the dax. Otherwise, you might imagine that in this story daxes deserve help and that Mary, a dax, gets help from Sally*).

Taxonomies: Many verbs have multiple meanings. For instance, *Mary touches Sally* can be interpreted as a contact event or as a psychological event. This not only complicates classifying the verb for taxonomic analysis, but introduces noise as different participants may interpret the verb differently, thus arriving at different IC biases. (Interestingly, despite the ubiquity of verbal polysemy, this issue does not appear to have been addressed previously in the IC literature.) Thus, for all analyses involving verb taxonomies we excluded all polysemous verbs, operationalized as verbs that fall into more than one VerbNet class, unless the sentence frame that was used in the study ruled out consideration of the additional class (e.g., because it requires an intransitive frame or an inanimate object), leaving us with 328 monosemic verbs, which we classified according to four well-known IC verb taxonomies:

Brown & Fish (1983a). The Brown & Fish taxonomy consisted of two types of psych verbs (experiencer-stimulus verbs and stimulus-experiencer verbs) and action verbs. Brown and Fish (1983a) do not give explicit definitions of these classes. Based on examples given by Brown and Fish, we assume psych verbs include all verbs of emotion (*fear, frighten*), cognition (*know, understand*) and perception (*see, hear*). Transitive psych verbs are easily identified in VerbNet: classes 30.1 (*detect, hear*), 30.2 (*discover, recognize*), 31.2 (*fear, love*), 32.1 (*covet,*

crave), 87.2 (*misinterpret, misunderstand*) are experiencer-stimulus and class 31.1 (*frighten, surprise*) is stimulus-experiencer. All other verbs were classified as action verbs.

Rudolph & Forsterling (1997) / McKoon et al. (1993). Rudolph and Forsterling (1997) adopt the Brown & Fish classifications of experiencer-stimulus and stimulus-experiencer verbs, but divide action verbs into agent-evocator and agent-patient verbs based on their implicit causality bias (the former are defined as object-biased; the latter, subject-biased). To make this a non-circular taxonomy, we follow Ferstl et al. (2011) in classifying the examples of agent-evocator verbs given by Rudolph and Forsterling (1997) according to VerbNet and then tagging all verbs in those classes as agent-evocator. The intuition here is that on any *semantic structure* account, verbs with similar meanings should have similar biases (and verbs within one VerbNet class have highly similar meanings). The only verb class exemplified by at least one monosemic verb was class 33 (*praise, slander*) (for polysemous verbs, it is impossible to know which meaning the authors intended to invoke). All other action verbs were classified as agent-patient. This results in a taxonomy identical to that proposed by McKoon et al. (1993).

It should be noted that Rudolph and Forsterling (1997) also include class 33 verbs in their list of agent-patient verbs (*slander*), and thus by the logic used above this class is *both* agent-patient and agent-evocator. However, the model with class 33 verbs as agent-evocator performs the best, and so that is the only one discussed below. Note that McKoon et al. (1993) specifically single out class 33 verbs (*praise, slander*) as object biased, and thus for them the problem does not arise.

Au (1986). Au's taxonomy is for most purposes identical to Rudolph and Forsterling's. There are two classes of action verbs: action-agent, defined as subject-biased action verbs,

and action-patient, defined as object-biased action verbs (again, psych verbs are handled identically to Brown and Fish). The primary difference is that Au provides more examples of verbs in the two action verb classes: all monosemic action-patient examples were either in VerbNet class 33 (*praise, slander*) or class 45.4 (*cool, improve*). As was the case with Rudolph and Forsterling, verbs from both these classes are also included in the subject-biased action-agent class. However, attempting to account for this leads to taxonomies that perform even more poorly and thus are not discussed further here.

Linguistic Category Model. The most comprehensive description of the Linguistic Category Model appears in Semin and Fielder (1991), who identify four types of verbs: *state verbs*, *state action verbs*, *descriptive action verbs* and *interpretive action verbs*. The first two classes appear to be identical to experiencer-stimulus and stimulus-experiencer verbs, respectively (the former "refer to mental and emotional states; no clear definition of beginning and end; do not readily take progressive forms; not freely used in imperatives" (p. 5), and the latter describe an "implicit action frame by the sentence subject that leads to the experience of a state in the object of the sentence" (p. 6)). The remaining verbs are either descriptive action verbs, which entail that the action have one physically invariant feature, or interpretive action verbs, which do not. The authors seem to have in mind a fairly liberal notion of what is "physically invariant". Examples of such verbs include *meet, summon, stop, prepare, visit* and *wake up* (Semin & Fiedler, 1988, 1991; Semin & Marsman, 1994). Interpretive action verbs are predicted to be subject-biased, whereas descriptive action verbs

are predicted to be non-biased. In order to avoid experimenter bias, we asked naive participants to code verbs according to the definitions described above.⁵

Results

We first provide a descriptive overview of the results. We then evaluate the predictions of each of the previous taxonomies. Finally, we evaluate a new taxonomy based on VerbNet.

Each verb was evaluated by an average of 47 participants. The distribution of results is shown in Figure 1, and results for each verb are presented in Appendix A. Across all 720 verbs, there was a slight overall bias in favor of choosing the object as the referent of *she* (overall object bias: 59.2%, SE=0.6%, $t(719)=15.93, p<.0001$). 37 verbs exhibited a significant subject bias ($p's \leq .05$) and 265 a significant object bias ($p's \leq .05$). Of these, 3 subject-biased and 93 object-biased verbs survive a conservative Bonferroni correction for 720 comparisons. Thus, the bulk of the verbs tested showed no strong bias, a fact confirmed by Hartigan dip test analyses (Hartigan & Hartigan, 1985) implemented in R (Maechler, 2009; R Development Core Team, 2009), which found no evidence of a bimodal distribution in IC bias (.009, $p>.9$). This is consistent with previous reports that many verbs do not elicit a systematic pronoun bias (Garvey et al., 1974; Semin & Fiedler, 1991).

We investigated whether this unimodality was due to noise in the distribution caused by polysemous verbs. After excluding all verbs with more than one possible use, the remaining 328 monosemic verbs again showed a broad distribution of biases (Figure 2) with a

⁵ The 328 monosemic verbs (see below) were divided into 8 lists. 12 English-speaking participants recruited through Amazon Mechanical Turk participated in each list, with 23 excluded for failing to follow directions.

slight overall object bias (58.4% choosing object, $SE=0.9\%$, $t(327)=9.48$, $p<.0001$). Again, there is no evidence of a bimodal distribution (Hartigan's $dip=0.015$, $p>.6$), again indicating that a significant proportion of the verbs showed no clear IC pronoun bias. This pattern is not attributable to the inclusion of verbs that are marginal for two animate arguments; many verbs that typically take two animate arguments (*troubles*, *commands*, *teaches*) showed no clear IC bias (see also Appendix A).

These results are problematic for previous taxonomies on which most or all verbs should exhibit IC biases (Table 1). We considered the IC biases for each of the classes in the four previous taxonomies. Because we are primarily interested in knowing whether verb class predicts IC bias better than the grand mean, and the grand mean in this experiment was object-biased, we compared the IC biases in each class to the grand mean for monosemic verbs (58.4%). While analyses based on these taxonomies confirmed that stimulus-experiencer psych verbs are subject-biased and experiencer-stimulus psych verbs are object biased -- a prediction common to Brown and Fish (1983a), Rudolph and Forsterling (1997), and the Linguistic Category Model (Semin & Fiedler, 1988, 1991) -- these taxonomies do not isolate non-psych verbs which are subject biased, and all but the Rudolph and Forsterling / McKoon et al. taxonomy fail to isolate non-psych verbs which are object biased (Table 2). This is despite the fact that many such verbs do have significant biases (Appendix A).

In the case of the Linguistic Category Model, we considered the possibility that naive participants did not have the metalinguistic knowledge to accurately distinguish descriptive action and interpretive action verbs. The first author recoded all 328 monosemic verbs twice: first with a relatively strict interpretation of Semin and Fiedler's (1991) definition of descriptive-action verbs, and second with a broader interpretation so as to include verbs of

communication (*cf* *summon* and *call* (Semin & Fiedler, 1988)). On the former (strict) taxonomy, again neither class was significantly biased. On the latter (broad) taxonomy, interpretive action verbs were again non-biased (Num.=214, $M_{diff}=-1\%$, $SD=16\%$, $t=1.07$, $p=.29$), while descriptive action verbs were significantly object-biased (Num.=66, $M_{diff}=+4\%$, $SD=13\%$, $t=2.31$, $p=.02$), in both cases contrary to predictions (Table 1). Note that even this latter effect was small, and only a slight majority of the verbs were numerically more object-biased than the grand mean (38 of 66).

Thus, when tested against a representative sample of verbs, none of the previous taxonomies discussed successfully picked out both subject- and object-biased action verbs.

VerbNet Verb Class Analyses

We classified the 328 monosemic verbs by VerbNet verb class in order to determine whether this more fine-grained analysis would reveal coherent subclasses with consistent IC biases. IC bias was modeled with a bi-directional stepwise linear regression, with any verb class for which at least five verbs were tested included as predictors. There were 11 such classes covering 135 of the 328 verbs. The resulting model ($R^2=0.2$) identified six verb classes, all of which exhibited significant biases (Table 3). The biases for the remaining five classes with at least five verbs were small ($<5\%$) and did not approach significance ($ts<1$). These classes were class 13.2 (*lose, relinquish*), class 13.5.1 (*attain, buy*), 13.5.2 (*accept, obtains*), class 30.1 (*detect, hear*), and class 48.1.2 (*define, exhibit*).

Comparison of Taxonomies

We next compare the accuracy of the predictions for the four taxonomies. Unlike the previous taxonomies, the VerbNet taxonomy makes no predictions about directionality (but see General Discussion); however it does predict that all verbs in a class should pattern

similarly. Thus, a verb was counted as conforming to predictions if its bias was the same as for the class as a whole (subject-, object- or neither). Verbs were counted as biased if $p < .10$ in a two-sided binomial test.⁶ The VerbNet taxonomy correctly classified 56% of verbs (excluding the 193 verbs for which the taxonomy currently makes no predictions). The four previous taxonomies only correctly classified from 28% to 31% (Table 4), primarily due to predicting subject biases for many non-biased or even object-biased verbs (Table 5).

Chance performance for each of the taxonomies was estimated using Monte Carlo simulation. The results for the verbs were randomly permuted 10,000 times, holding each taxonomy's predictions constant. Thus chance performance could be estimated while accounting for the fact that each taxonomy made different predictions about the base rates of subject- and object-biases.

All taxonomies performed significantly above chance ($ps < .05$). For most of the taxonomies, this success was attributable entirely to correctly predicting the biases for classes 31.1 (*frighten, surprise*) and 31.2 (*fear, love*), about which all taxonomies to create. With those words excluded, only the Rudolph & Forsterling / McKoon et al. and the VerbNet taxonomies performed above chance ($ps < .001$), with the latter still performing considerably better overall (Table 4).

Discussion

⁶ Note that the Linguistic Category Model was credited with predicting no bias for descriptive action verbs. Its performance drops if it is considered to have predicted subject biases for those verbs.

The four previous taxonomies fared quite poorly when tested against a representative sample of verbs. In particular, as they predict that most or all verbs should have significant IC biases, whereas most do not. These taxonomies cannot be much improved by changing the predictions from some of the verb classes from “biased” to “non-biased”, as the taxonomies would still fail to pick out biased action verbs, of which there are many. These taxonomies do better on psych verbs, but remain far from perfect.

In contrast, the VerbNet analyses pick out four classes of non-biased action verbs (classes 13.2 (*love, relinquish*), 13.5.1 (*attain, buy*), 13.5.2 (*accept, obtain*), and 48.1.2 (*define, exhibit*)) and three classes of biased action verbs (classes 33 (*praise, slander*), 45.4 (*cool, improve*), and 59 (*compel, dare*)), more accurately capturing the pattern of results. Moreover, the results for the biased classes are remarkably uniform: in class 33 (*praise, slander*), 14 of 18 verbs were numerically object-biased and in class 59 (*compel, dare*) all six verbs were numerically subject-biased. Class 45.4 (*cool, improve*) was less consistent, with 18 of 28 verbs numerically subject-biased. It should be noted that many verbs in this class are only marginally acceptable with two animate arguments (e.g., *improves*), which may have contributed to its unreliability. It should also be noted that while VerbNet largely agrees with the previous taxonomies in terms of psych verbs, with experiencer-stimulus verbs being object-biased and stimulus-experiencer verbs being subject biased, there was one class of experiencer-stimulus verbs for which there was no strong evidence of bias (class 30.1 (*detect, hear*)). Given that only a small number of verbs in that class were tested (six), one cannot rule out the possibility of sampling/measurement error, but the possibility of finer-grained distinctions between experiencer-stimulus psych verbs merits further research.

Experiment 2

The above results demonstrate that IC bias varies systematically with respect to the fine-grained verb classes identified by VerbNet. But the semantic structure hypothesis makes a stronger prediction. To the extent that IC biases are caused solely by differences in verb semantics, we should expect all verbs in a given class to show similar IC biases. The existing data sets are not well-suited for testing this prediction. Most studies have used a small set of verbs that were specifically selected because they were believed to have a strong object or subject bias (Rudolph & Forsterling, 1997). Experiment 1 avoids the problem of selection bias, but is not well designed to test the consistency of IC biases within a given verb class for two reasons. First, the study is exploratory in the sense that the bias of each class was determined empirically based on the behavior of its members (rather than predicted *a priori*). Second, most verb classes contained fewer than 20 verbs and thus minimal information was available about the distribution of verbs within a class. Finally, on average fewer than 50 judgments were collected for each verb. As the judgments were binary, this limited resolution plus sampling error means that our estimates of individual verbs' biases were relatively imprecise, potentially smearing the distribution of IC biases within any given class. Thus, in Experiment 2, we collect substantially more judgments per verb in order to minimize measurement error and sample a much larger number of verbs within a given class to test consistency.

Specifically, in Experiment 2, we collected IC judgments on all the verbs in class 31.1 (*frighten, confuse*) and 31.2 (*fear, love*) that were listed in Levin (1993). There were three reasons for selecting these two classes for further analysis. First, both are large classes thus providing us with sufficient verbs to provide a strong test of within-class uniformity. Second, unlike the verbs in some of the other classes (e.g., 45.4 (*cool, improve*)), these verbs are readily used with both an animate subject and an animate object, resulting in more natural stimuli.

Third, these classes make up the bulk of transitive psych verbs and psych verbs have been played a central role in both IC research and in the study of argument realization (Au, 1986; Brown & Fish, 1983a, 1983b; Dowty, 1991; Ferstl et al., 2011; Goikoetxea, Pascual & Acha, 2008; Greene & McKoon, 1995; Jackendoff, 1990; Levin, 1993; Levin & Rappaport Hovav, 2005; Pesetsky, 1995; Pinker, 1989; Rudolph & Forsterling, 1997; Semin & Fiedler, 1988, 1991; Semin & Marsman, 1994; Talmy, 2000a, 2000b). While it is widely believed that class 31.1 (*frighten, surprise*) verbs are uniformly subject-biased while class 31.2 verbs (*fear, love*) are uniformly object-biased, only a handful of such verbs have been tested and whether the results are truly general is unknown.

Psych verbs are problematic for theories of argument realization because these verbs appear to involve the same thematic roles but they vary in how they express them (experiencer-stimulus or stimulus-experiencer). Within IC research there is a robust consensus that the IC bias of psych verbs follows the STIMULUS (Brown & Fish, 1983a, 1983b; Rudolph & Forsterling, 1997); nonetheless non-negligible numbers of exceptions have been reported (Ferstl et al., 2011; Goikoetxea et al., 2008). And indeed, in Experiment 1 we found one class of experiencer-stimulus verbs (30.1 (*detect, hear*)) which showed no systematic IC bias. Thus we cannot assume that biases are consistent within the class 31.1 (*frighten, surprise*) or class 31.2 (*fear, love*). In addition, some theorists have proposed that the variability in argument realization in psych verbs reflects differences in their meaning which could potentially influence their IC bias. For example, Pesetsky has suggested that the subject of a *frighten* verb is actually the CAUSE of the emotion while the object of a *fear* verb is merely the TARGET of this emotion. This might lead us to expect strong consistency across verbs among class 31.1 (*frighten, surprise*) but more variability within class 31.2 (*fear, love*) verbs.

Method

Participants: Participants were recruited and tested online through coglanglab.org. We included only the 1,025 participants (mean age: 30, SD=13) who completed the experiment, were native English speakers, and reported not having participated in the experiment previously.

Materials and Procedure: There are considerably more class 31.1 (*frighten, surprise*) verbs (220) than class 31.2 (*fear, love*) verbs (44). Thus, if stimuli were randomized, participants would see primarily class 31.1 verbs, which by hypothesis are subject-biased. This risks priming subject resolution, distorting the phenomenon of interest. Thus, each participant was presented with 12 verbs randomly selected without replacement from each of two verb classes, resulting in an average of 56 judgments for each *frighten* verb and 280 judgments for each *fear* verb.

Results and Discussion

Analyses below use the grand mean of 58.4% object bias as our conservative “chance” threshold. Individual verb results are presented in Appendix B; the distributions are shown in Figure 3. In contrast to Experiment 1, the distribution was clearly bimodal (Hartigan’s $dip=0.036, p<.05$). Class 31.1 (*frighten, surprise*) showed a strong subject bias (35.7% object bias, SE=1.0%, $t(219)=14.86, p<.01$), while class 31.2 (*fear, love*) showed a strong object bias (81.5% object bias, SE=1.1%, $t(43)=28.53, p<.01$), and the two classes were significantly different from one another $t(262)=31.27, p<.01$.

All class 31.2 (*fear, love*) verbs exhibited object-biases, 41/44 significantly so (39/44 after Bonferroni correction), while 202/220 class 31.1 verbs (*frighten, surprise*) exhibited

subject-biases, 170 significantly so (110 survive Bonferroni correction).⁷ Only 6 of the latter showed significant object biases (1 after Bonferroni correction). Thus, semantic class was a very strong predictor of the IC pronoun bias, consistent with the *semantic structure* account.

As in Experiment 1, we conducted further analyses focusing on monosemic verbs as defined by VerbNet. The resulting distribution was again bimodal (Hartigan's *dip*=0.040, $p<.02$; Figure 4). Of the remaining 171 class 31.1 (*frighten, surprise*) verbs, all but 7 (*wounds, dejects, cows, alienates, discourages, placates, torments*) exhibited a subject bias, 142 significantly (95 after Bonferroni correction; See Figure 4). Only one class 31.1 *frighten* verb (*alienate*) was significantly object biased, and not after Bonferroni correction. All but 1 (*stands*) of the 36 remaining class 31.2 (*fear, love*) verbs were significantly object-biased (33 after Bonferroni correction). Moreover, there was no overlap between the distributions of the two classes, with the exception of *alienate*.

Thus, while Experiment 1 and previous studies (e.g., Ferstl et al., 2011; Goikoetxea et al., 2008) found considerable overlap in the distributions for the broadly-defined experiencer-stimulus and stimulus-experiencer classes, class 31.1 (*frighten, surprise*) and class 31.2 (*fear, love*) verbs are categorically different in their behavior. Importantly, we find that this categoricity extends beyond the relatively small number of verbs that have been repeatedly tested.

⁷ All 44 class 31.2 (*fear, love*) verbs were significantly different from the 50% chance threshold, even after Bonferroni correction. Using the 50% threshold necessarily raises the bar for subject-biases. Nonetheless, 184 class 31.1 (*frighten, surprise*) verbs still show a numeric subject bias (130 significantly), 34 an object bias (12 significantly), and 2 no bias.

General Discussion

Experiments 1 and 2 demonstrate that implicit causality (IC) biases in pronoun interpretation vary systematically across semantic classes of verbs that are independently motivated based on patterns of argument realization. In Experiment 1 and the reanalysis of Ferstl et al. (2011), we investigated 11 different verb classes, finding significant biases 6 of them. In Experiment 2, we investigated two of these classes – class 31.1 (*frighten, surprise*) and class 31.2 (*fear, love*) -- finding that the IC bias was consistent for the vast majority of members in both classes. We also found converging results from a reanalysis of data from 305 verbs reported by Ferst et al. (2011) (see Appendix C). These findings suggest that IC bias varies systematically with coherent, independently-defined verb classes. These results also demonstrate why previous IC verb taxonomies have shown inconsistent results: these taxonomies collapsed across different sets of verbs that exhibit systematically different biases. Indeed, we find when applied to large sets of verbs, these older taxonomies are close to or at chance in predicting IC bias.

These results are fully consistent with the *semantic structure* hypothesis, which directly predicts a systematic relationship between semantic structure and IC bias. Our findings are not directly predicted or explained by alternate accounts, such as the *arbitrary semantic tag* or *world knowledge* accounts. However, these hypotheses could be amended or extended to account for these findings, thus below, we explore how these alternative accounts are constrained by the present data. First, however, we discuss theories of semantic structures of verbs that could potentially support causal inferences and consider whether IC bias is continuous or categorical.

The Semantics of Verbs

VerbNet verb classes are defined syntactically but are argued to represent coherent semantic classes (*cf* Levin & Rappaport Hovav, 2005). We suggested above that the semantics of these classes signal -- directly or indirectly -- who caused the event or state described by the verb. This information, in combination with expectations about the content of the subordinate clause introduced by *because* (Brown & Fish, 1983a; Garvey & Caramazza, 1974; Garvey et al., 1974; Kehler et al., 2008) would provide a straightforward representational basis for the observed pronoun bias.⁸ In this section, we describe two frameworks that have been proposed for representing the semantics of verbs (thematic roles and predicate decomposition, described below) and discuss how each might explain the relevant data. This is an active area of research: there many competing thematic role and predicate decomposition theories and consensus on the correct description of verbal semantics is a long way off. Thus our goal in this section is simply to describe whether and how such theories could, in principle, account for IC bias. Nonetheless, it is easiest to describe classes of theories by outlining specific examples. The most fully implemented thematic role theory and most fully-implemented predicate decomposition theory are both found in VerbNet.

Thematic roles

⁸ Early discussions of IC implicitly assumed that a subordinate clause introduced by *because* necessarily encodes the cause of the event in the main clause. More recently, several authors have suggested that *because* introduces an explanation, rather than a cause *per se* (Kehler, 2002; Kehler et al., 2008; Pickering and Majid, 2007). Either account is consistent with the analysis here, since explanations by necessity are more likely to refer to entities that were causally responsible for an event (Kehler, 2002; Kehler et al., 2008).

Thematic roles are invoked in linguistic theory to help explain how the different arguments of the verb are syntactically encoded in a clause (for review, see Levin & Rappaport Hovav, 2005). For example, thematic roles are invoked to explain which argument of a two-place predicate will surface as the syntactic subject (e.g., in *Sally broke the vase*, Sally is an AGENT and AGENTS are mapped onto subject position). Starting with Brown and Fish (1983a), several previous *semantic structure* accounts invoked thematic roles to explain IC: namely, some thematic roles are inherently causal (e.g., AGENT, STIMULUS), and thus comprehenders expect entities filling those roles (like Sally in *Sally frightened Mary*) to be the “implicit” cause of the event in question. The data and analyses above suggest these theories were insufficiently nuanced to capture patterns in IC biases. Interestingly, modern thematic role theorists have typically found it necessary to posit far more than the 4-5 thematic roles employed in previous IC theories in order to account for differences in verb semantics and syntactic behavior. VerbNet, for example, utilizes 33 different thematic roles. Perhaps this more extensive set of thematic roles will be able to capture IC bias patterns.

We explored this possibility in two ways. First, we analyzed the monosemic verbs from Experiment 1, coded for VerbNet thematic roles, excluding 68 verbs for which VerbNet suggested more than one set of thematic roles.⁹ Each thematic role was entered into a bi-directional stepwise linear regression composed of main effects only with each thematic role

⁹ An example is the verb *dry* (class 45.4). In *Bill dried the clothes*, VerbNet codes *Bill* as an AGENT and *the clothes* as a PATIENT. In *The hairdryer dried the clothes*, VerbNet codes *the hairdryer* as an INSTRUMENT and *the clothes* as a PATIENT. Note that the issue here is not purely animacy: animate beings can be used as instruments (*John wiped the floor with Bill*).

as a predictor, coded as a “1” if the thematic role appeared in subject position, as a “-1” if it appeared in object position, and a “0” otherwise. The resulting model contained three thematic roles: EXPERIENCER (equivalent to Brown and Fish’s (1983a) thematic role of the same name), PRODUCT (an entity that is created during the event, as in the object of *design*, *rationalize* or *rebuild*), and STIMULUS (the object of cognition and perception verbs – note that this is a small subset of the relevant verbs in Brown and Fish’s (1983a) taxonomy), all of which were significant predictors of bias ($ps < .05$).¹⁰ Surprisingly, all predicted that the pronoun would be resolved to the *other* argument. Thus, if there are thematic roles which always attract pronoun resolution, this method combined with this particular thematic role theory could not identify them.

However, it may be that IC bias cannot be predicted directly from the thematic role borne by an argument, but by the causal strength of that thematic role relative to the thematic role borne by the other verbal argument. We investigated this possibility in our second analysis. We used the Batchelder-Bershad-Simpson scaling method (Batchelder, Bershad & Simpson, 1992) to estimate a hierarchy for the thematic roles investigated above (Figure 5).¹¹ This statistical technique has been widely used to estimate dominance hierarchies in social animals based on the outcomes of dyadic interactions (Jameson, Appleby & Freeman, 1999)

¹⁰ One additional thematic role (THEME) was retained in the stepwise regression but was not itself a significant predictor ($t(160)=1.53, p=.13$).

¹¹ Additionally, we excluded 12 verbs, discussed further below, for which both arguments bore the same thematic role. A total of 235 verbs remained.

and is based on a method introduced for ranking chess players (Elo, 1978). Note that an advantage of this method is it does not require two thematic roles to have actually appeared with the same verb in order to estimate which is more highly ranked. Thus, CAUSE is ranked higher than STIMULUS not because CAUSE-STIMULUS verbs are known to be biased towards the patient (no such verbs exist), but because CAUSE-EXPERIENCER verbs are strongly biased towards the cause (these are the class 31.1 (*frighten, surprise*) verbs), whereas EXPERIENCER-STIMULUS verbs are only weakly biased towards the STIMULUS (these are class 30.1 (*detect, hear*) and 30.2 (*discover, recognize*) verbs). Note that, unlike in the IC literature, VerbNet does not classify the non-EXPERIENCER argument of class 31.2 (*fear, love*) verbs as a STIMULUS; rather, this is a THEME, a categorization typical in linguistics (see Levin & Rappaport Hovav, 2005). This explains the relatively high ranking of THEME, as such verbs are strongly biased in favor of the THEME.

The resulting thematic hierarchy (Figure 5) successfully predicted the numeric direction of bias for 60% of the relevant verbs – far better than the more coarse-grained thematic role theories employed by Brown and Fish (1983a), Au (1986) or Rudolph and Forsterling (1997), and on par with the VerbNet verb classes, despite having considerably fewer degrees of freedom than the latter. This fit would likely improve if we allowed that verbs for which the arguments are in similar positions in the hierarchy should be non-biased. We leave implementation of this for future research. We further note that much of the hierarchy is intuitively correct, with CAUSE being the most causal and PRODUCT – an entity which does not exist prior to the event and thus cannot have caused the event – being the least causal.

Nonetheless, there are some limitations to this hierarchy. One would expect that if both arguments of the verb bore the same thematic role, the verbs would be unbiased. However,

the seven verbs (*better, dominate, exceed, generate, overcome, own, possess*) which had a THEME in both subject and object position were on average subject-biased ($t(6)=3.44, p=.01$).

Similarly, the five verbs (*divorce, embrace, fight, marry, visit*) listed with ACTOR in both positions were on average object-biased ($t(4)=2.99, p=.04$). Similarly, not all of the rankings on the hierarchy can be clearly independently motivated. That is, there is no clear reason that RECIPIENT should be less causal than EXPERIENCER. It should be reiterated that the hierarchy in Figure 5 is a function not just of our data, but of the thematic role theory implemented by VerbNet. Whether other thematic role theories can successfully address these limitations is a question for further research.

Predicate Decomposition

Predicate decomposition theories have emerged in part to address limitations in the explanatory power of thematic role theories, such as the fact that neither the exact list of thematic roles nor the fact that many possible thematic role combinations in any given language are unattested (English has no CAUSE-STIMULUS verbs) is left unexplained and must be stipulated (Levin & Rappaport Hovav, 2005). Such theories decompose the semantics of a verb into more primitive predicates, and it is these predicates that assign functions to the arguments of the verb (e.g., Harley, 1995; Jackendoff, 1990; Moens & Steedman, 1988; Pinker, 1989; see Levin & Rappaport Hovav, 2005, for a thorough discussion). For instance, when used transitively, verbs from class 31.1 (*frighten, surprise*) might be decomposed as

- (13) class 31.1: NP1 V NP2
 CAUSE(NP1, E) EMOTIONAL_STATE(RERESULT(E), EMOTION, NP2)

That is, such verbs have two arguments (NP1 and NP2) and describe two things: 1) NP1 causes event E, and 2) an emotional state is experienced by NP2 as a result of event E. In *Sally*

frightened Mary, Sally is NP1, Mary is NP2, and fright is the EMOTION. Depending on the account, NP1 is realized as the sentential subject because it is the argument of CAUSE, because it is the least-embedded argument in the semantic structure, or for some other reason (Levin & Rappaport Hovav, 2005), but on any such account *Sally frightened Mary* literally means that Sally caused Mary to be afraid, straightforwardly predicting a subject IC bias. Importantly, on this theory all verbs in a class share the same semantic structure. The only difference between members of class 31.1 (*frighten, surprise*) is what type of EMOTION is entered into this semantic structure. Thus all verbs in a class should have the same IC bias.

VerbNet suggests the following structures for class 45.4 (*cool, improve*) and class 59 (*compel, dare*), the other two subject-biased VerbNet classes identified above:

(14) class 45.4: NP1 V NP2

CAUSE(NP1, E) STATE(RESULT(E), ENDSTATE, NP2)

(15) class 59: NP1 V NP2

FORCE(DURING(E), NP1, NP2, ?PROPOSITION)

In the case of class 45.4 (*cool, improve*), once again the subject of the verb is marked as the cause of the event described by the verb, thus accounting for the IC bias.¹² In the case of class

¹² An individual verb may be able to appear in multiple semantic structures. For instance, class 45.4 is also compatible with the following semantic structure, which is linked to an intransitive syntactic frame:

(16) NP1 V

STATE(RESULT(E), ENDSTATE, NP1)

59 (*compel, dare*), the subject is marked as forcing the object to adopt a proposition or state, and is thus similarly causal.

The object-biased class 31.2 (*fear, admire*) has a very different structure. While some theorists have suggested that the object of class 31.2 (*fear, love*) verbs is also a cause (Jackendoff, 1990; Pinker, 1989), VerbNet does not analyze it in this way (see also Pesetsky, 1995). Instead the structure it provides treats the emotional state as arising “in reaction to” the verb’s object (17). If we assume that *react to* is the inverse of *cause to*, then we can conclude that the object of *fear* has semantic properties that are similar to the subject of *frighten*, explaining the IC bias.

(17) class 31.2: NP1 V NP2

EMOTIONAL_STATE(E, EMOTION, NP1) IN_REACTION_TO(E, NP2)

The object-biased class 30.2 (*discover, recognize*) similarly involves the IN_REACTION_TO component:

(18) class 30.2: NP1 V NP2

PERCEIVE(DURING(E), NP1, NP2) IN_REACTION_TO(E, NP2)

Thus, the syntactic frames that a verb can appear in reduces to the semantic structures a verb is compatible with, which explains -- on this account -- why identifying verb classes with syntactic criteria leads to semantically coherent verb classes. A challenge for such theories, then, is to fully account for why each verb is compatible with certain semantic structures and not others (e.g., Levin & Rappaport Hovav, 1988; Pinker, 1989).

Levin (1993) suggests a similar structure for class 33 (*praise, slander*, see also McKoon et al., 1993):

These verbs share some properties with the *admire*-type psych-verbs [e.g., class 31.2 verbs] ... While the *admire* verbs relate to a particular feeling that someone may have in reaction to something, these verbs relate to judgment or opinion that someone may have in reaction to something. (Levin, 1993, p. 196)

Thus, IC bias for these classes can be accounted for by the predicate decomposition schema already implemented in VerbNet, though considerable additional work is required to demonstrate that it *does* explain IC bias. For instance, while it is asserted that classes 31.1 (*frighten, surprise*), 30.2 (*discover, recognize*) and 33 (*praise, slander*) all contain the same IN_REACTION_TO component in their semantic structure, there does not appear to be any independent motivation for proposing that these verbs have this structure. In addition, VerbNet gives the same predicate decomposition to both classes 30.1 (*detect, hear*) and 30.2 (*discover, recognize*), while we find different IC biases for the two. Future research will need to address these issues.

Predicate Decomposition and Discourse Structure.

Both thematic role and predicate decomposition theories provide frameworks within which IC bias can be explained with reference to verbal semantics. Whether either will ultimately be sufficient is an open question (see also below). One reason to favor predicate decomposition at the outset is that the richer structures invoked may be more successful at accounting for the effects of different connectives. As noted above, pronoun resolution biases are a complex interaction of the verb and connective (Crinean & Garnham, 2006; Ehrlich, 1980; Kehler et al., 2008; Stewart et al., 1998):

- (19) a. Sally₁ frightened Mary₂ because she₁...
 b. Because Sally₁ frightened Mary₂ she₂...

- c. Sally₁ frightened Mary₂, and then she₁
- (20) a. Sally₁ feared Mary₂ because she₂...
- b. Because Sally₁ feared Mary₂ she₁...
- c. Sally₁ feared Mary₂, and then she₁
- (21) a. Sally₁ criticized Mary₂ because she₂...
- b. Because Sally₁ criticized Mary₂ she₂...
- c. Sally₁ criticized Mary₂, and then she₁

Kehler et al. (2008) suggest that the different connectives set up different expectations about discourse continuations, and thus different aspects of the verb's semantics become relevant. Thus, in (19a), (20a), and (21a), the second clause explains the first and thus the pronoun should refer to the cause of the situation. In (19b), (20b), and (21b), the second clause refers to a consequence of the situation in the first, and thus the pronoun should refer to the affected entity to whom the consequence occurs. In (19c), (20c), and (21c), the two clauses describe a succession of events; in such cases, subjects tend to co-refer and verbal semantics is less relevant. Note that the pattern is different for the different verbs: while for *criticize*, the cause and affected entity are the same, for *frighten* and *fear*, they are different. While this can be described in terms of thematic roles (e.g., Stevenson, Crawley & Kleinman, 1994), the fact that predicate decomposition straightforwardly allows the same argument to bear multiple roles with respect to the verb may account for these patterns more naturally.

Continuous vs. Discrete Distributions of Bias

Several researchers have commented on the fact that IC bias appears to be continuously distributed, rather than bimodal (Garvey et al., 1974; Semin & Fiedler, 1991), and indeed in Experiment 1 we observed verbs at a wide range of IC biases. This fact is

sometimes taken as evidence in favor of the *world knowledge* account, on which bias is necessarily graded, and against the *semantic structure* account, as early versions (e.g., Brown & Fish, 1983) predicted more categorical results.

A number of factors can mask underlying categoricity. First, categoricity may be masked by measurement error. Moreover, since the analyses above suggest that if IC bias is categorical, then there are at *least* three categories -- subject-biased, object-biased and non-biased – and sampling from these three categories with some measurement error would give the appearance of a continuous distribution. This would be exacerbated if different verb *classes* have different strength biases. Thus, it may be that the underlying semantics of class 45.4 (*cool, improve*) is less causal than the semantics of class 31.1 (for instance, perhaps class 45.4 involves indirect causation, and class 31.1, direct causation). This would make the overall distribution look even more continuous.

Second, polysemous verbs may have one meaning that leads to one bias and another meaning that leads to another. Confusion over interpretation on the part of the participants would then lead to weaker biases in proportion to the confusion, further causing an apparent continuous distribution. Although we eliminated many polysemous verbs, we likely did not eliminate them all as polysemy itself is an open area of research. Similarly, some verbs were less natural in the sentential contexts employed, which could weaken participant intuitions. Finally, although IC bias is one factor in pronoun resolution, it is by no means the only (Ferstl et al., 2011; Kehler et al., 2008; Nappa & Arnold, 2009), and these other factors may affect different verbs differently, further smearing the distribution.

Thus, although a continuous distribution is often seen as evidence for the *world knowledge account*, in fact it is also consistent with the *semantic structure account*. However,

the two theories account for such a distribution differently, and it remains for future work to tease these issues apart.

Revisiting world knowledge and semantic features

While the *world knowledge* account and the *arbitrary semantic tag* account do not predict the effects of semantic structure, both accounts are in principle compatible with them. The semantic verb classes that we investigated are thought to reflect systematic differences in the conceptualization of different types of events. Presumably the event concepts that underlie this semantic knowledge are also involved in representing our knowledge of typical (or specific) events in the world and their causes. Thus, on any hypothesis, we would expect to see a correlation between semantic verb classes and the contents of world knowledge, and so if one patterns with IC bias, the other will, too. Similarly, on the arbitrary tag hypothesis, the semantic tag of each verb must be learned, presumably on the basis of the utterances in which the verb appears. Since these utterances will describe specific events, as filtered through the human conceptual system, this information will be shaped by the same forces that have given rise to semantic verb classes and to our world knowledge.

However, the three proposals make quite different claims about the processes involved in IC biases and the means by which they are acquired. On the *semantic structures* hypothesis, the argument structure that is associated with a class of verbs encodes information that is relevant to inferring the causes of events. Consequently IC can often be read off of the semantic representation of an utterance; once one has learned what a verb means, the IC bias comes for free. On the other two accounts, a verb's definition is insufficient. Thus, the most direct way to distinguish between these accounts would be to conduct studies in which

participants are taught new verbs under conditions that controlled their knowledge of semantic structure, linguistic experience and event knowledge.

With all this in mind, it is worth revisiting the most commonly-cited evidence in favor of the *world knowledge* hypothesis: evidence that factors such as gender and social dominance relations affect IC judgments (Corrigan, 2001; LaFrance et al., 1997; Maass et al., 1989; Mannetti & De Grada, 1991). For instance, Corrigan (2001) found that participants were more likely to declare the object responsible in sentences like (22) than in sentences like (23), presumably because traitors are seen as more deserving of criticism than kings.

(22) The monarch criticized the traitor.

(23) The traitor criticized the monarch.

The *world knowledge* account explains that listeners access statistical knowledge about why monarchs and traitors criticize one another to ultimately decide who was the most likely cause. On the *semantic structure* and *arbitrary semantic tag* accounts, listeners initially determine who the cause was linguistically, but upon reflection, the listener can also access world knowledge about traitors and monarchs, and this may suggest additional hypotheses about what caused the event of criticism, modifying the original assessment.

Since it is possible to track moment-to-moment adjustments in listener's online assessments of pronoun resolution (Arnold, Eisenband, Brown-Schmidt, & Trueswell, 2000; Arnold, Brown-Schmidt, & Trueswell, 2007; Pyykkonen & Jarvikiivi, 2010; Pyykkonen et al., 2010), pronoun resolution may be a particularly good place to look for distinctions in how different sources of information that influence IC bias are integrated online, though no such studies have been run.

Conclusion

This investigation of fine-grained semantic verb classes represents a promising direction in the study of IC and pronoun resolution in general. Previous investigations that have considered semantic verb classes have focused on coarse-grained distinctions, which typically resulted in only 3 or 4 verb classes (Rudolph & Forsterling, 1997). With few exceptions the verb classes employed were based on intuitions about the causal structure encoded in the verb and thus were not independently motivated (but see Semin & Fiedler, 1988, 1991). The present study demonstrates that verb classification schemes based on syntactic patterns correlate with – and potentially explain – the direction of implicit causal biases.

These results suggest that we should be cautious in using IC to probe people’s causal knowledge of world (Au, 1986; Corrigan & Stevenson, 1994; De Goede et al., 2009; Maass et al., 1989). To the extent that IC biases reflect knowledge linguistic structure, they may provided a distorted picture of a person’s nonlinguistic world knowledge. For example, measures of IC may overestimate children’s understanding of causation (Au, 1986; Corrigan & Stevenson, 1994) if children are able to derive the semantic structures of verbs from tracking their syntactic properties (Gleitman, 1990) but do not fully understand the causal properties of the event types that they encode.

On a methodological level, this study considerably increases the number of English verbs for which IC biases have been reported (see Ferstl et al., 2011; Rudolph & Forsterling, 1997). By making these data publically available (see the appendixes) we hope to facilitate the creation of new experiments (see Goikoetxea et al., 2008, for a similar project in Spanish)

Finally, this discovery potentially provides a new probe into the semantic structures of verbs. The study of verb meaning within linguistics has focused largely on what constructions

(e.g., dative, double object, progressive, etc.) a given verb can appear in. If these concerns are directly related to IC – and our analyses above suggest that they are – then implicit causal biases may provide a new data point to inform this project.

APPENDIX C: Re-analysis of Ferstl et al. (2011)

In order to test the reliability of our findings, we reanalyzed the 305 verbs reported in Ferstl, et al. (2011). Participants in that study completed sentence fragments (*Sally frightened John because...*), and IC bias was calculated based on who the continuations referred to (Sally or John), which was typically unambiguous because of the use of a gendered pronoun (*he* or *she*). The authors first selected 109 verbs from previous studies (Au, 1986; Crinean & Garnham, 2006; Rudolph, 2008). They classified these verbs according to Levin's (1993) verb classes (a precursor to VerbNet) and chose additional verbs from those classes.

Results and Discussion

Results were re-analyzed following the analyses in Experiment 1. We identified 211 monosemic verbs with a mean object bias of 49.3%, which was used as the baseline for subsequent analyses (see Experiment 1). We first conducted analyses according to the Brown and Fish taxonomy, the Rudolph and Forsterling / McKoon et al. taxonomy, the Au taxonomy, and the Linguistic Category Model (Table C1). As predicted, experiencer-stimulus verbs were object-biased and stimulus-experiencer verbs were subject biased. Brown & Fish's action verbs are significantly object-biased, contrasting both with the theory's prediction and the results of Experiment 1. Au's action-agent verbs and Rudolph and Forsterling / McKoon et al.'s agent-patient verbs are non-biased, rather than subject-biased as predicted. The first author coded the Ferstl et al. (2011) verbs both according to the broad interpretation and the narrow interpretation of the Linguistic Category Model's descriptive action verbs (see Experiment 1 method). On the narrow interpretation, descriptive action verbs were non-biased ($t < 1$) and interpretive action verbs were significantly object-biased ($t = 4.88, p < .00001$). On the broad interpretation, descriptive action verbs -- which are predicted to be non-biased or weakly

subject-biased -- were significantly object-biased, whereas interpretive action verbs -- predicted to be subject-biased -- were non-biased.

We then reanalyzed this data according to the VerbNet verb classes. We found 92 verbs in class 31.1 (*frighten, surprise*), 33 in class 31.2 (*fear, love*), 48 in class 33 (*praise, slander*), 7 in class 36.2 (*court, cuddle*), and no more than 4 in each of 20 additional classes. As in Experiment 1, results were fit stepwise bi-directionally to a linear model with these classes as predictors. Classes 31.1 (*frighten, surprise*), 31.2 and 33 (*praise, slander*) emerged as significant predictors. Class 31.1 was significantly subject-biased, and classes 31.2 and 33 (*praise, slander*) were significantly object-biased (Table C2), replicating results from Experiment 1. Class 36.2 (*court, cuddle*), which consists largely of verbs of courtship, showed no significant bias ($M_{\text{diff}}=-8\%$, $SD=18\%$, $t=1.10$, $p=.31$).

These results explain why the two versions of the Linguistic Category Model produced different results. Most class 33 verbs (*praise, slander*) involve communication, which on the narrow interpretation were classified as Interpretive Action verbs (communication may proceed in oral or written form and thus has no physically invariant component), and which on the broad interpretation were classified as Descriptive Action Verbs (following the examples given by the authors, which include communication verbs like *summon*). Thus, whichever class included class 33 verbs (*praise, slander*) was object-biased. Thus the descriptive action/interpretive action distinction appears to be doing no work beyond what is done by identifying class 33 (*praise, slander*).

Thus, the reanalysis of Ferstl et al. (2011) confirms several important conclusions from Experiments 1 and 2. First, the finding of strong consistent biases for three VerbNet classes – 31.1 (*frighten, surprise*), 31.2 (*fear, love*), and 33 (*praise, slander*) – was replicated. Second,

while previous taxonomies roughly characterize psych verbs correctly, they all made incorrect predictions about action verbs. Moreover, the Brown and Fish taxonomy, the Au taxonomy, and the Linguistic Category Model taxonomy all saw the direction of bias for at least one class change relative to Experiment 1. This does not appear to be random variation but due to the fact that the biases of verbs vary systematically *within* verb classes used by these taxonomies. Thus, Au's action-patient verbs were more object-biased in the Ferstl et al. data relative to Experiment 1 because the former included a larger proportion of class 33 verbs (*praise, slander*). Brown and Fish's action verb class changed from non-biased (Experiment 1) to object-biased (Ferstl et al., 2011) for the same reason. Similar considerations apply to the Linguistic Category Model. While the Rudolph and Forsterling taxonomy fares somewhat better, it is still unable to distinguish subject-biased and non-biased action verbs, and if there are any additional classes of object-biased action verbs, it would be unable to identify those as well. Thus, the value of utilizing more narrowly-defined verb classes such as those in VerbNet is confirmed.
